## Abstract

Searches for the Standard Model Higgs boson have been performed in the data collected by the DELPHI experiment at LEP in the year 2000 at centre-of-mass energies between 200 and 209 GeV corresponding to a total integrated luminosity of 224 pb<sup>-1</sup>. No evidence for a Higgs signal is observed in the kinematically accessible mass range, and a 95% CL lower mass limit of 114.3 GeV/c<sup>2</sup> is set, to be compared with an expected median limit of 113.5 GeV/c<sup>2</sup> for these data. © 2001 Elsevier Science B.V. ---

## 1. Introduction

The LEP accelerator was successfully operated at e<sup>+</sup>e<sup>-</sup> collision energies up to 209 GeV during the

year 2000. The DELPHI experiment has collected more than 224 pb<sup>-1</sup> at centre-of-mass energies above 200 GeV, extending the range of searches for the Standard Model Higgs boson above the previous limits obtained by DELPHI [1–3], by the other LEP collaborations, and by their combination by the LEP Higgs Working Group [4].

---

<sup>1</sup> Now at DESY-Zeuthen, Platanenallee 6, D-15735 Zeuthen, Germany.

The results shown in this Letter are based on the detector calibration obtained shortly after the end of data taking. They will be included in the preliminary combination of the LEP collaborations results on the 2000 year data [5], being prepared by the LEP Higgs Working group [6].

### 1.1. Data and simulation samples

The data used in this analysis, corresponding to a total of  $224.1 \text{ pb}^{-1}$  collected by the DELPHI detector in 2000, were analysed in the following subsamples:  $2.3 \text{ pb}^{-1}$  at an average centre-of-mass energy of 202.6 GeV,  $6.7 \text{ pb}^{-1}$  at 203.9 GeV,  $10.5 \text{ pb}^{-1}$  at 204.8 GeV,  $62.5 \text{ pb}^{-1}$  at 205.2 GeV,  $18.2 \text{ pb}^{-1}$  at 206.2 GeV,  $115.2 \text{ pb}^{-1}$  at 206.7 GeV and  $8.7 \text{ pb}^{-1}$  at 208.2 GeV.

Monte Carlo samples for background events were produced at fixed centre-of-mass energies of 202, 204, 205, 206, 207 and 208 GeV using the same simulation setup as for the 1999 analysis [1]. The samples correspond to about 200 times the collected luminosity.

Similarly, signal events were produced using the HZHA [7] generator, varying the Higgs boson mass from  $85 \text{ GeV}/c^2$  to  $120 \text{ GeV}/c^2$  in  $5 \text{ GeV}/c^2$  steps, plus a fine scan in the most interesting zone, with samples simulated for mass hypotheses 108, 110, 112, 114 and  $115 \text{ GeV}/c^2$ .

### 1.2. Detector overview

A detailed description of the DELPHI apparatus can be found in [8]. For the first three quarters of the year the detector was operated in nominal conditions.

Data collected after the 1st of September, corresponding to the last  $60 \text{ pb}^{-1}$ , were affected by the complete failure of one sector (S6) of the TPC detector, which amounts to  $1/12$  of the TPC acceptance. Charged particle tracks crossing this sector were reconstructed using the information from the Vertex, Inner and Outer detectors, so the effect on the efficiency is limited. A complete sample of background and signal channels simulated with this TPC sector off was used to incorporate the small effect on the reconstructed event kinematics and the impact on the b-tagging efficiency into the analysis of this data sample.

To follow more precisely the change of conditions during the data taking, the calibration of the impact pa-

rameter resolution was performed with the high energy four-jet events. The same procedure was applied to the simulation where the four-jet events were selected with the same criteria and appropriately weighted according to the predicted cross-sections of the corresponding processes.

The calibration of the b-tagging used the tracks with negative impact parameter, while only the tracks with positive impact parameter were used in the lifetime based b-tagging.

The number of tracks with negative impact parameter is not affected by the calibration, and is used as further information in the b-tagging. Therefore this calibration procedure is not correlated with the physics measurement, while it improves significantly the agreement between data and simulation.

The overall performance of the combined b-tagging in hadronic radiative return events ( $e^+e^- \rightarrow Z^0 \gamma$ ), collected during the year 2000, is illustrated in Fig. 1.

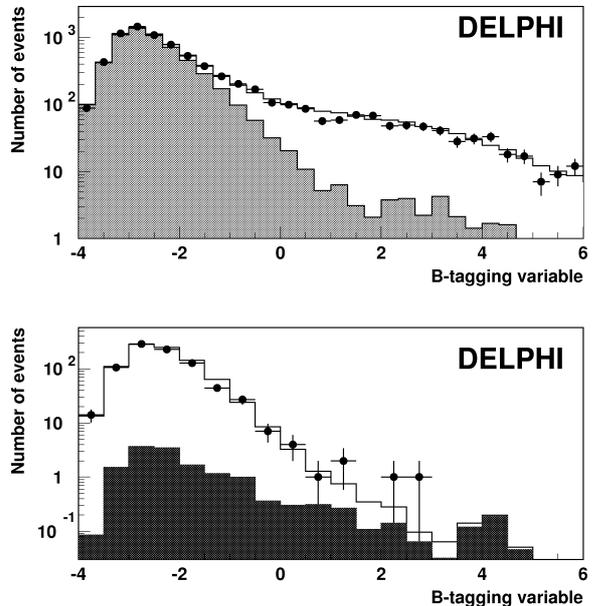

Fig. 1. Top: distributions of the combined b-tagging variable, for the year 2000 radiative return  $Z\gamma$  data (dots) and simulation (histogram). The expected contribution of  $udsc$ -quarks and non- $q\bar{q}\gamma$  background is shown as the dark histogram. Bottom: same distribution for semileptonic  $W^+W^-$  high energy events in the 2000 data. The shaded histogram corresponds to the expected contribution from other processes, and shows the high purity of the selection.

Effects of possible imperfect modelling of the high b-tag tail from non-b quarks were checked using the high energy semileptonic  $W^+W^-$  data and are also shown in Fig. 1.

## 2. Standard Model Higgs search

The previous LEP combined limit [4] on the Higgs mass at 95% CL was close to  $108 \text{ GeV}/c^2$ . Given the integrated luminosity corresponding to the data taken in the year 2000, the analysis is expected to cover efficiently the mass range up to the kinematical limit allowed by the increase in centre-of-mass energy.

The following improvements for this high mass range have been introduced in the analysis of the two main channels.

The four-jet analysis benefits from a better tuned b-tagging procedure and although it keeps the same event variables in the analysis, the discriminant neural network has been optimized for the high mass hypotheses.

The missing-energy channel includes a tighter preselection and additional variables in the likelihood, resulting in a better background rejection for a high mass Higgs; it is described in the following section.

### 2.1. $H\nu\bar{\nu}$ channel

In this channel both the preselection and the final discriminating likelihood have been reoptimised in the spirit of a “background free” analysis. A set of stringent cuts [9] was applied prior to the construction of the likelihood.

The discriminating likelihood includes six variables defined after forcing the event into a two-jet configuration with the DURHAM [10] algorithm: acoplanarity, acollinearity, polar angle of the missing momentum with respect to the beam direction, b-tagging, invariant mass in the transverse plane, the minimum of the energies around the most isolated particle and around the most energetic particle (normalised to their own energy). Three more variables are defined leaving the number of jets free in the DURHAM algorithm with  $y_{\text{cut}} = 0.005$ : the minimum angle between the jet directions and the missing momentum

in the transverse plane, the minimal jet charged multiplicity, and the maximum track or reconstructed lepton transverse momentum with respect to the jet axis.

The effect of the preselection on data and simulated samples is shown in Table 1. After a tighter cut to select the most significant candidates, three candidate events remain, while 4.9 are expected according to the background simulation.

Distributions for the most relevant variables in this analysis are shown both at preselection level (Fig. 2), and at the tight selection level (Fig. 3).

The reconstructed Higgs boson mass is defined as the visible mass given by a one-constraint fit where the recoil system is assumed to be an on-shell  $Z^0$  boson. It is used, together with the discriminant likelihood, in the two-dimensional computation of the confidence levels for the Higgs hypotheses.

### 2.2. Leptonic channels

Higgs boson searches in events with jets and leptons follow the analysis applied to the 1999 data [1], which included a  $\sqrt{s}$  dependence in the corresponding preselections. The effect of the selections on data and simulated samples is detailed in Table 1. Good agreement between data and background simulation at the preselection level is observed in all the leptonic channels.

In the  $He^+e^-$  channel, 7 candidate events are selected in the data, for a total expected background of 11.6 events coming mainly from the  $e^+e^-q\bar{q}$  process. In the  $H\mu^+\mu^-$  channel, 7 events are selected and 10.6 background events are expected coming mainly from the  $\mu^+\mu^-q\bar{q}$  process. Both channels use the b-tagging value as the discriminant variable and the fitted hadronic mass in the two-dimensional calculation of the confidence levels. One of the  $He^+e^-$  and two of the  $H\mu^+\mu^-$  candidates have a significant b-tagging value but are kinematically compatible with the ZZ hypothesis.

In the  $\tau^+\tau^-q\bar{q}$  channel, 5 candidates are selected, while 6.0 are expected from the Standard Model background, which is dominated by the ZZ into  $\tau^+\tau^-q\bar{q}$  process. Two events are selected after a cut on the discriminant likelihood at 0.1; neither has a high value for the rescaled mass.

Table 1

Effect of the selection cuts on data, simulated background and simulated signal events. The two main background contributions are detailed. Efficiencies are given for a signal of  $m_H = 114 \text{ GeV}/c^2$ . Candidates selection indicates the number of events used as input to the confidence level calculations. The tight selection is obtained after a further cut in the corresponding discriminant variable, and corresponds to the one used in the mass plot (Fig. 7)

Selection	Data	Background	$q\bar{q}(\gamma)$	4-fermion	Efficiency, %
$H\nu\bar{\nu}$ channel					
Preselection	970	880	467	390	67
Candidates selection	90	99.7	50.4	49.3	60
Tight selection	3	4.9	1.4	3.5	30
$He^+e^-$ channel					
Preselection	1242	1172	745	416	78
Candidates selection	7	11.6	0.5	10.4	57
Tight selection	1	3.5	0.1	3.2	49
$H\mu^+\mu^-$ channel					
Preselection	3780	3763	2671	1067	81
Candidates selection	7	10.6	0.2	10.4	67
Tight selection	2	3.6	0.1	3.5	56
$\tau^+\tau^-q\bar{q}$ channel					
Preselection	9180	8913	5425	3468	98
Candidates selection	5	6.0	0.4	5.6	22
Tight selection	2	4.1	0.1	4.0	19
$Hq\bar{q}$ channel					
Preselection	2266	2342	680	1662	85
Candidates selection	398	423.7	154.9	268.8	79
Tight selection	8	7.4	2.8	4.6	36

### 2.3. Higgs boson searches in four-jet events

Higgs boson searches in fully hadronic final states start with a common four-jet preselection [2,3], which eliminates hard radiative events and reduces the  $q\bar{q}(\gamma)$  and  $Z\gamma^*$  background, forcing all selected events into a four-jet topology with the DURHAM algorithm.

The performance of the DELPHI b-tagging procedure in the four-jet analysis was specially optimized and enhanced by taking into account the dependence on additional variables related to the kinematical properties of b-hadrons produced in decays of the Higgs boson. These variables, defined for each jet in the event, are: the polar angle of the jet direction, the jet

energy, the charged multiplicity of the jet, the angle to the nearest jet, the average transverse momentum of charged particles with respect to the jet direction, the number of particles with negative impact parameter and the invariant mass of the jet. Including this dependence in the tagging algorithm significantly improves the rejection of the light quark background. The global b-tagging value of the event is defined as the maximum b-tagging value for any di-jet in the event, computed as the sum of the corresponding jet b-tagging values.

The final discriminant variable used in the four-jet channel is defined as the output of an artificial neural network (ANN) which combines 13 variables.

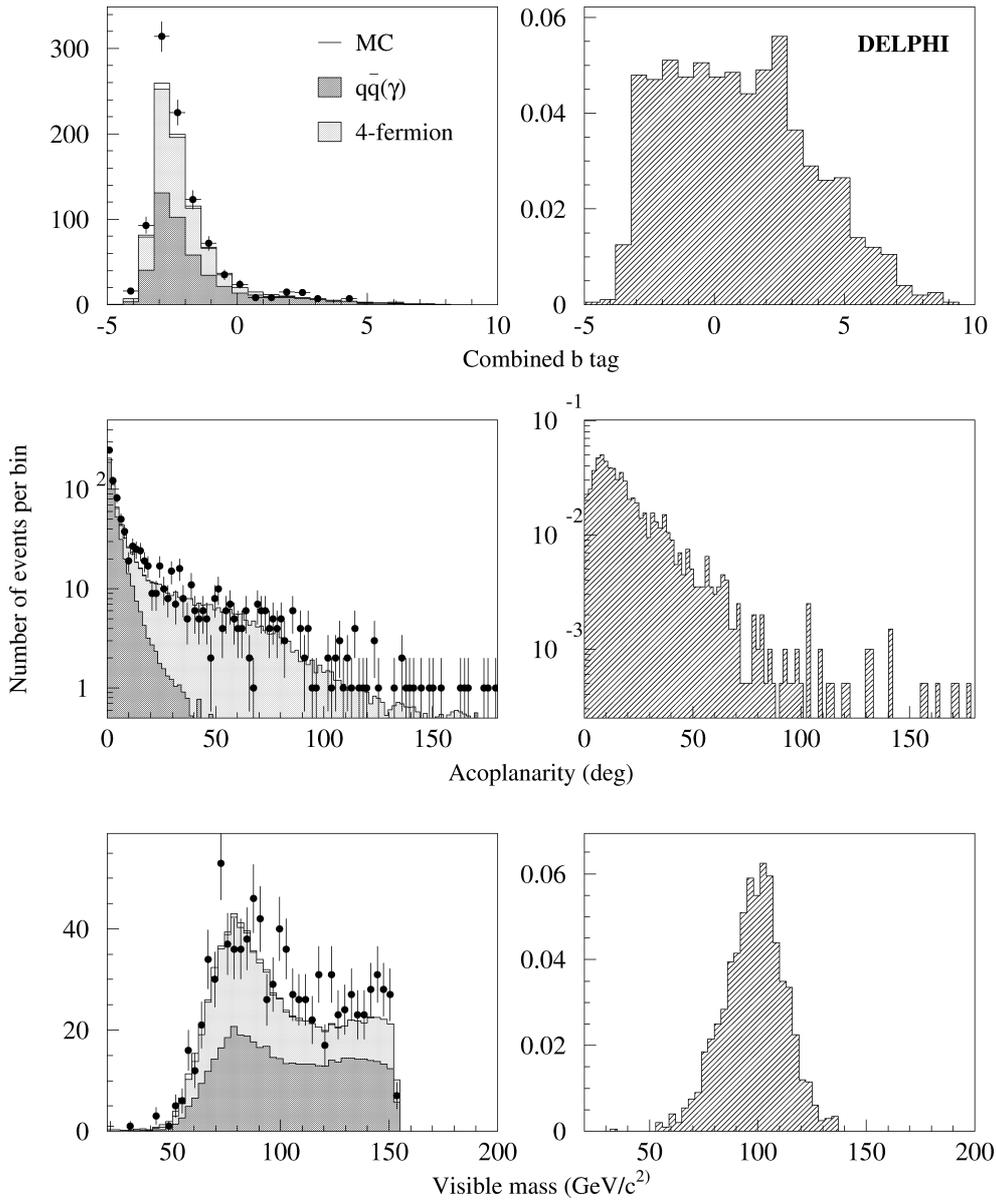

Fig. 2.  $H\nu\bar{\nu}$  channel: distributions of relevant analysis variables, at the preselection level. Data at  $\sqrt{s} = 200\text{--}209$  GeV (dots) are compared with Standard Model background expectations (left-hand side histograms) and with the expected distribution for a  $114\text{ GeV}/c^2$  Higgs mass signal (right-hand side histogram).

The first variable is the global b-tagging value of the event.

The next four variables rely on kinematics and test the compatibility of the event with the hypotheses of  $W^+W^-$  and  $ZZ$  production to either 4 or 5 jets.

Constrained fits are used to derive the probability density function measuring the compatibility of the event kinematics with the production of two objects of any masses. This two-dimensional probability, the ideogram probability [11], is then folded with the

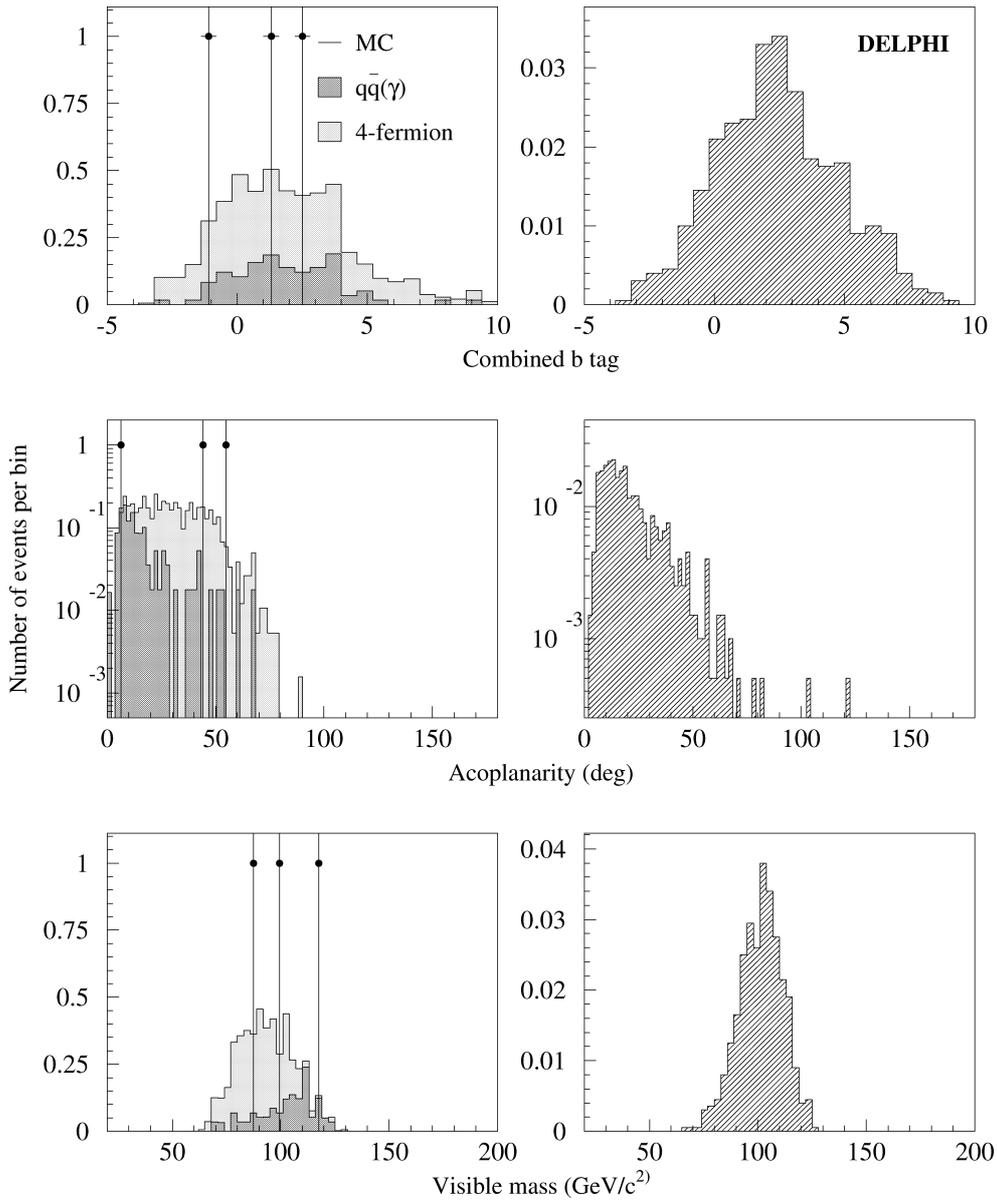

Fig. 3.  $H\nu\bar{\nu}$  channel: same distributions as in Fig. 2 but at the tight selection level.

expected mass distributions for the  $W^+W^-$  and  $ZZ$  processes, respectively.

Finally, the last eight input variables intended to reduce the  $q\bar{q}(\gamma)$  contamination are the sum of the second and fourth Fox–Wolfram moments, the product of the minimum jet energy and the minimum opening angle between any two jets, the maximum and

minimum jet momenta, the sum of the multiplicities of the two jets with lowest multiplicity, the sum of the masses of the two jets with lowest masses, the minimum di-jet mass and the minimum sum of the cosines of the opening angles of the two di-jets when considering all possible pairings of the jets. In the previous analysis [1] these eight variables were

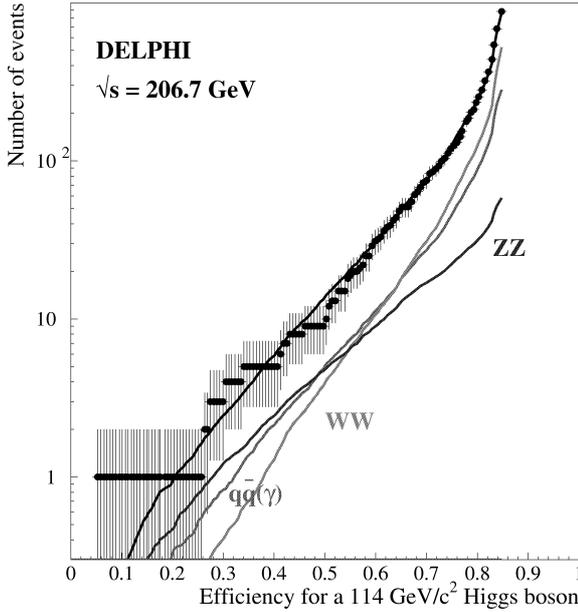

Fig. 4.  $Hq\bar{q}$  channel: Expected Standard Model background rate at a centre-of-mass energy  $\sqrt{s} = 206.7$  GeV as a function of the efficiency for a  $114 \text{ GeV}/c^2$  Higgs mass signal when varying the cut on the neural network variable. The different background contributions are shown summed and separately. Dots stand for data.

separately combined in an anti-QCD artificial neural network.

Fig. 4 shows the performance of the final discriminating variable in the efficiency-background plane for a  $114 \text{ GeV}/c^2$  signal at  $\sqrt{s} = 206.7$  GeV.

The choice of the Higgs di-jet makes use of both the kinematical 5C-fit probabilities and the b-tagging information in the event [3]. The likelihood pairing function,

$$\begin{aligned} & \mathcal{P}_b^{j_1} \cdot \mathcal{P}_b^{j_2} \cdot ((1 - R_b^Z - R_c^Z) \cdot \mathcal{P}_q^{j_3} \cdot \mathcal{P}_q^{j_4} \\ & + R_b^Z \cdot \mathcal{P}_b^{j_3} \cdot \mathcal{P}_b^{j_4} + R_c^Z \cdot \mathcal{P}_c^{j_3} \cdot \mathcal{P}_c^{j_4}) \cdot P_{j_3, j_4}^{5C} \end{aligned}$$

is calculated for each of the six possibilities to combine the jets  $j_1, j_2, j_3$  and  $j_4$ .  $\mathcal{P}_b^{j_i}, \mathcal{P}_c^{j_i}, \mathcal{P}_q^{j_i}$  are the probability densities of getting the observed b-tagging value for the jet  $j_i$  when originating from a  $b, c$  or light quark, estimated from simulation.  $R_b^Z$  and  $R_c^Z$  are the hadronic branching fractions of the  $Z^0$  into  $b$  or  $c$  quarks, and  $P_{j_3, j_4}^{5C}$  is the probability corresponding to the kinematical 5C-fit with the jets  $j_3$  and  $j_4$  assigned to the  $Z^0$ . The pairing that maximises this function is selected. The proportion of right matchings for the

Higgs di-jet, estimated in simulated signal events with  $114 \text{ GeV}/c^2$  mass, is around 53% at preselection level, increasing to above 70% at the tighter level, keeping a low rate of wrong pairings for ZZ background events.

The good agreement between data and background simulation after the four-jet preselection is illustrated in Fig. 5 which shows the distributions of the global b-tagging, the two ideogram probabilities for the configuration with 4 jets, and the output of the anti-QCD ANN. The results for the different selection levels are given in Table 1. The tighter cut at an ANN value of 0.7 selects 8 events in data while 7.4 are expected from the background simulation. Fig. 6 shows the previous variables at this level.

#### 2.4. Confidence level estimation

The confidence levels for the background ( $CL_b$ ) and signal plus background ( $CL_{s+b}$ ) hypotheses are defined as the probability in the two cases of observing a likelihood ratio  $\mathcal{Q}$ , greater than or equal to that measured in the data [12]. The confidence level for the signal case is calculated consistently with the LEP Higgs Working group using the conservative ratio  $CL_s = CL_{s+b}/CL_b$ .

The likelihood ratio for a given Higgs mass hypothesis is defined as  $\ln(\mathcal{Q}) = -S + \sum_i \ln(1 + s_i/b_i)$  where  $S$  is the total expected signal, and  $s_i$  and  $b_i$  are the signal and background probability densities for each candidate  $i$ , calculated using two-dimensional information, where one dimension is the reconstructed Higgs boson mass and the other is the channel dependent discriminant variable.

These densities are represented as two-dimensional histograms which are derived from the simulation samples described in Section 1.1. These distributions are then smoothed using a two-dimensional kernel, which is essentially Gaussian but with a small longer tailed component. The width of the kernel varies from point to point, such that the statistical uncertainty on the estimated background is never more than 30%. The same width is applied to background and all signal samples to eliminate the possibility of the smearing itself increasing the estimated signal to background ratio. Finally the distribution is reweighted so that when projected onto either axis it has the same distribution as would have been observed if the smoothing had been only in one dimension. This makes better use of

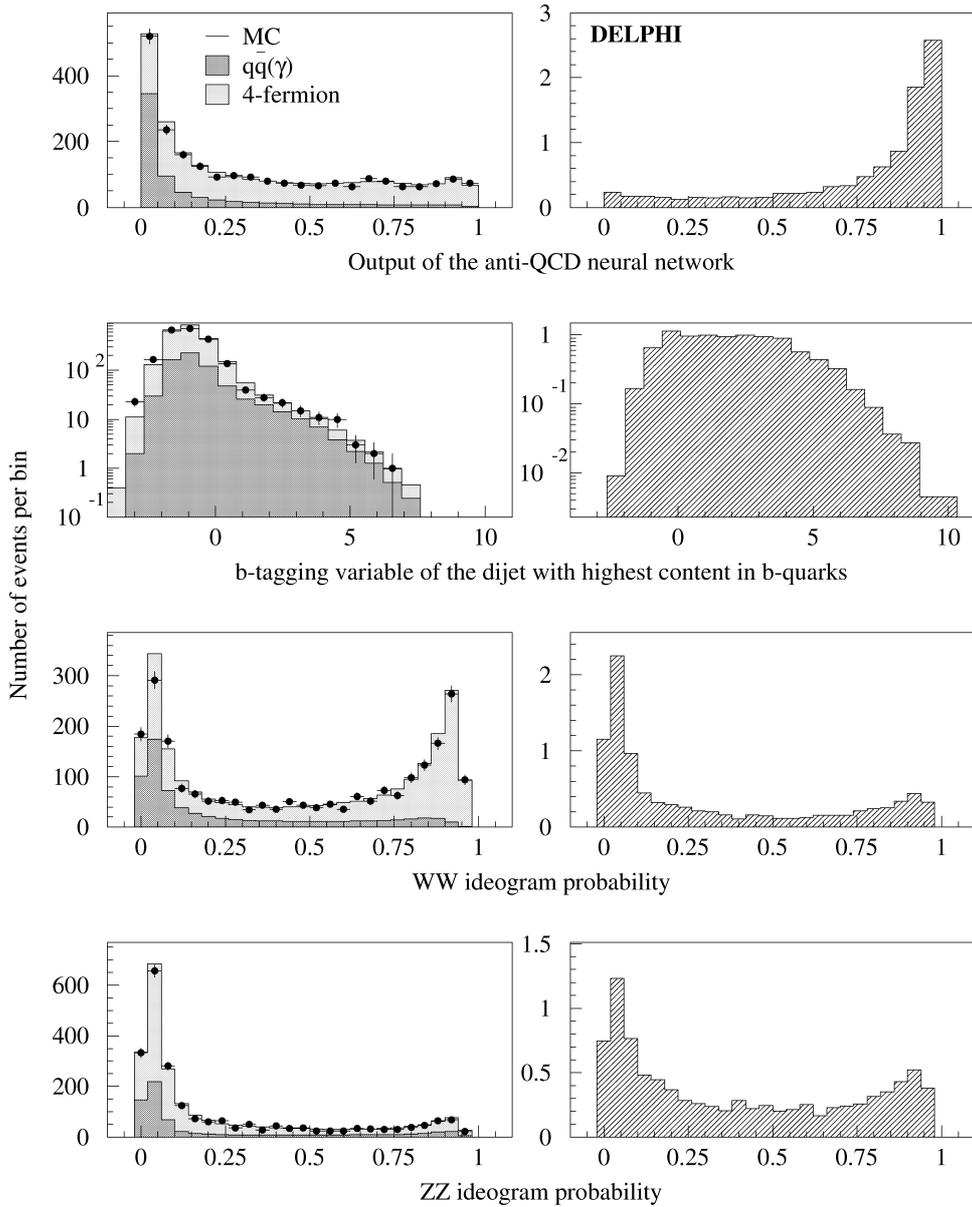

Fig. 5.  $Hq\bar{q}$  channel: distributions of relevant analysis variables at the preselection level. The eight variables used to reduce the  $q\bar{q}(\gamma)$  background are summarized by the output of the anti-QCD neural network. Data at  $\sqrt{s} = 200\text{--}209$  GeV (dots) are compared with Standard Model background expectations (left-hand side histograms) and with the expected distribution for a  $114\text{ GeV}/c^2$  Higgs mass signal (right-hand side histogram).

the simulation statistics if there are features which are essentially one dimensional, such as mass peaks, and it has been verified that the systematic errors introduced are significantly smaller than the statistical ones.

The resultant two-dimensional distributions are then linearly interpolated from the simulation conditions to the appropriate beam energy and Higgs mass hypotheses.

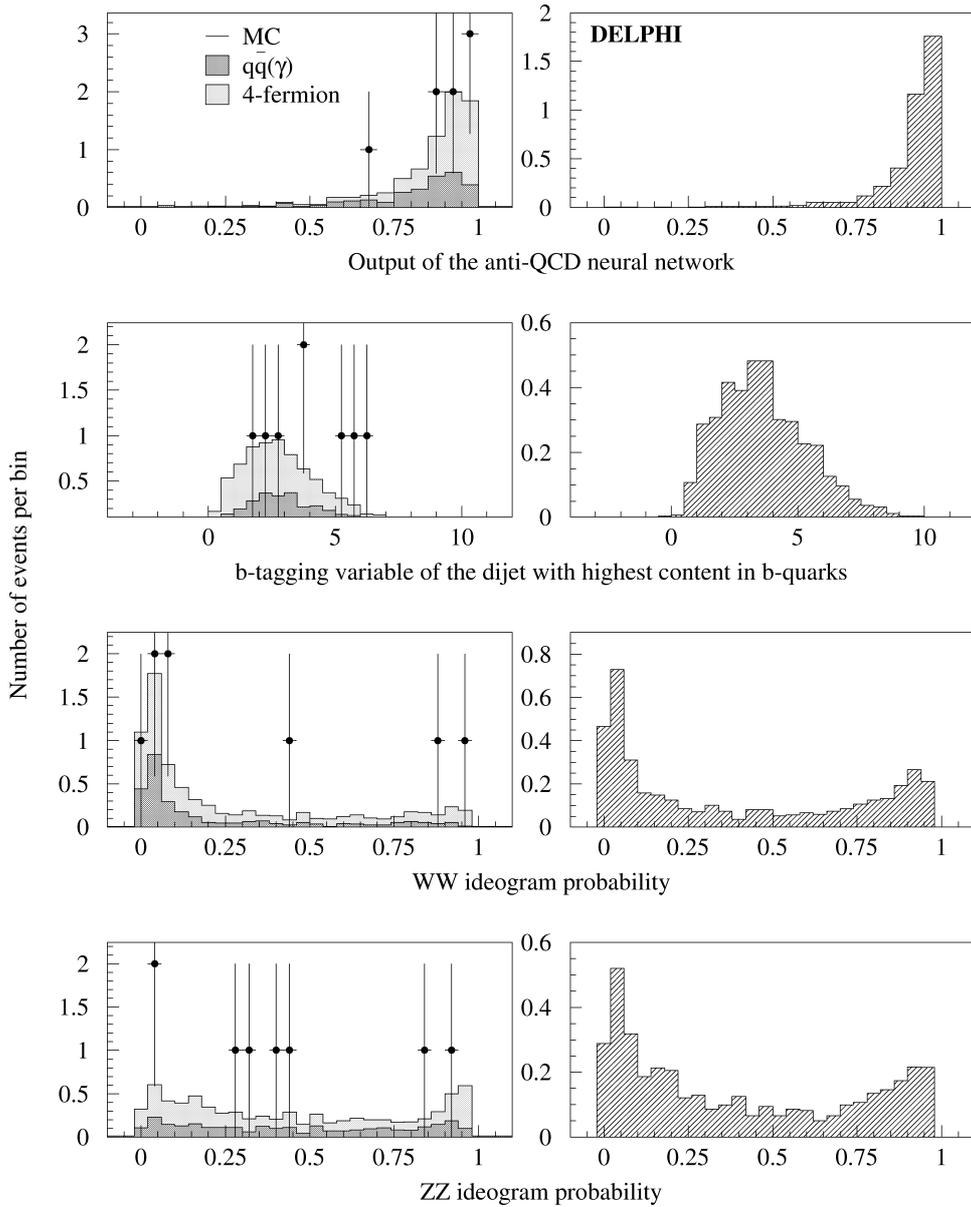

Fig. 6.  $Hq\bar{q}$  channel: same distribution as in Fig. 5 but at the tight selection level.

### 3. Results

The distribution of the reconstructed Higgs boson mass summed over all channels, at the level of the tight selection, is presented in Fig. 7.

The limit on the Standard Model Higgs boson mass is set combining the data analysed in the previous

sections with those taken at lower energies, namely 161 and 172 GeV [13], 183 GeV [3], 189 GeV [2] and 192–202 GeV [1].

The confidence level for the signal hypothesis  $CL_s$  is shown in Fig. 8, as well as the confidence level for the background hypothesis in the form  $1-CL_b$ . A slight deficit with respect to the expected background is

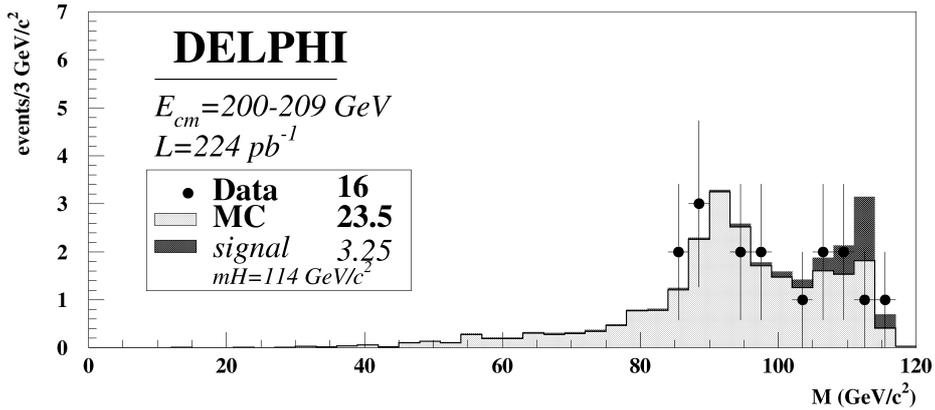

Fig. 7. Distribution of the reconstructed mass of the candidates when combining all HZ analyses at 200–209 GeV in the year 2000. Data (dots) are compared with the Standard Model background expectations (light shaded histogram) and with the normalised  $114 \text{ GeV}/c^2$  signal spectrum added to the background contributions (dark shaded histogram).

observed, and a 95% CL lower limit on the mass is set at  $114.3 \text{ GeV}/c^2$ , while the expected median is  $113.5 \text{ GeV}/c^2$ . The test-statistic (negative log-likelihood ratio) is shown in Fig. 9.

It has been noticed that the combined LEP result [6] is better described if a Higgs boson with mass  $115 \text{ GeV}/c^2$  is present. For such a signal, the DELPHI  $\text{CL}_{s+b}$  value is 3%, while the  $\text{CL}_b$  is 23%. The  $\text{CL}_s$  for this hypothesis is 12%, so that the present data are not incompatible with the existence of a Higgs boson with this mass. This can also be seen in Fig. 9, where the result is compared with the probability density for background and background plus signal experiments.

#### 4. Conclusions

The data taken by DELPHI at 200–209 GeV in the year 2000 have been analysed to search for the Standard Model Higgs boson. The data for all channels is compatible with expectations from the Standard Model background. In combination with previous DELPHI results at lower centre-of-mass energies, a lower limit at 95% CL on the mass of the Standard Model Higgs boson is set at  $114.3 \text{ GeV}/c^2$ , while the expected median limit is  $113.5 \text{ GeV}/c^2$ .

#### Acknowledgements

We are extremely grateful to the members of CERN-SL Division for their expertise and dedication that has allowed the LEP energy to be increased well beyond the design value, with a consequent extension of the search for the Higgs boson. We are greatly indebted to our technical collaborators and to the funding agencies for their support in building and operating the DELPHI detector.

We acknowledge in particular the support of Austrian Federal Ministry of Science and Traffics, GZ 616.364/2-III/2a/98; FNRS-FWO, Flanders Institute to encourage scientific and technological research in the industry (IWT), Belgium; FINEP, CNPq, CAPES, FUJB and FAPERJ, Brazil; Czech Ministry of Industry and Trade, GA CR 202/96/0450 and GA AVCR A1010521; Commission of the European Communities (DG XII); Direction des Sciences de la Matière, CEA, France; Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie, Germany; General Secretariat for Research and Technology, Greece; National Science Foundation (NWO) and Foundation for Research on Matter (FOM), The Netherlands; Norwegian Research Council; State Committee for Scientific Research, Poland, 2P03B06015, 2P03B11116 and SPUB/P03/DZ3/99; JNICT-Junta Nacional de Investigação Científica e Tecnológica, Portugal; Vedecka grantova agentura MS SR, Slo-
